FINDINGS IN PHYSICAL EXAMINATION OF THE EXTERNAL GENITALIA IN PEDIATRIC AGE – DIFFERENT IS NOT ALWAYS PATHOLOGICAL - PART II (FEMALE)

ALTERAÇÕES AO EXAME FÍSICO DO APARELHO GENITAL EM IDADE PEDIÁTRICA - O QUE É DIFERENTE NEM SEMPRE É PATOLÓGICO – PARTE II (FEMININO)

Nuno Teles Pinto¹, Diana Morais Costa², Ana Sofia Marinho³, João Moreira Pinto¹,⁴

ABSTRACT

Introduction: Findings in the physical examination of the external genitalia in children are often a source of concern and anxiety for parents and caregivers. Due to the proximity and role in child’s periodic surveillance, the family physician is in a privileged position to identify and initially provide guidance on these situations, key for the success of future interventions.

Objectives: To review available evidence on the main variations and anomalies of the external female genitalia in pediatric age, focusing on diagnosis and clinical approach in primary health care.

Results: In most cases, anomalies of the prepubertal female external genitalia are only variants of normal and/or do not significantly affect function, hence not requiring intervention other than clinical surveillance – e.g., fusion of labia minora. However, others require referral to secondary health care – like congenital vaginal obstruction or clitoral hypertrophy –, with early intervention being crucial for the success of implemented measures in some cases.

Conclusion: Genital pathology in prepubertal children is most often diagnosed by systematic and careful physical examination and usually has a favorable outcome. It is important to distinguish variants of normal from situations requiring more specialized assessment, in order to optimize health care system resources without overloading it and decrease parental anxiety.

Keywords: child; female; genitalia; urogenital abnormality

RESUMO

Introdução: Os achados no exame físico da genitália externa em crianças são frequentemente uma fonte de preocupação e ansiedade para pais e cuidadores. Devido à proximidade e papel na vigilância periódica da criança, o médico de família encontra-se numa posição privilegiada para a identificação e orientação inicial destas situações, chave para o sucesso das intervenções.

Objetivos: Rever a evidência disponível sobre as principais variações e anomalias da genitália externa do sexo feminino em idade pediátrica, com foco no diagnóstico e abordagem clínica nos cuidados de saúde primários.

Resultados: Na maioria dos casos, as anomalias prépuberais da genitália externa feminina são apenas variantes do normal e/ou não afetam significativamente a função, não necessitando de outras intervenções para além de vigilância clínica, como é o caso da fusão dos pequenos lábios. No entanto, existem outras situações que requerem referênciação para os cuidados de saúde secundários, como é o caso

da obstrução vaginal congênita ou hipertrofia do clítoris, sendo que em alguns casos a intervenção precoce é essencial para o sucesso das medidas implementadas.

**Conclusão:** A patologia genital na criança pré-púbere é mais frequentemente diagnosticada através de um exame físico sistemático e cuidadoso e, na maioria dos casos, tem um resultado final favorável. É importante distinguir variantes do normal de situações que requerem avaliação mais especializada, de modo a otimizar os recursos do sistema de saúde sem o sobrecarregar e diminuir a ansiedade dos pais.

**INTRODUCTION**

Findings in the physical examination of the external genitalia in children are often a source of concern for parents and caregivers, not only due to the emotional significance people attribute to these structures – in part for their role in the reproductive function –, but also to the potential physical and psychological impact on the child.

Due to the role in the child’s close monitoring and periodic surveillance, the family physician has a crucial role in identifying and initially guiding these situations. Physical examination is a fundamental part of the child’s regular clinical evaluation and usually the most useful and effective tool for establishing a specific diagnosis. Variants of normal with maintenance of normal physiological function are the most frequent cases, not requiring intervention other than clinical surveillance and reassurance. However, some cases require medical intervention, frequently in the secondary health care setting, with early intervention being key for success of implemented measures.

As the family physician is often responsible for diagnosing these anomalies, he/she should be informed about guidelines for each particular situation, not only for reassuring parents in cases without pathological significance, but also for properly and timely referring the child to secondary health care, when necessary.

**OBJECTIVES**

To review available evidence and discuss the diagnosis, medical approach, and guidance at primary health care of the principal anomalies of the female external genitalia in pediatric age. Discussion of anomalies related to sexual differentiation disorders is beyond the scope of this article, since they are frequently diagnosed in hospital setting and have a highly specific approach.

**CHANGES IN PHYSICAL EXAMINATION OF THE FEMALE GENITAL TRACT**

**Fusion/coalescence of labia minora**

Fusion of labia minora, also designated labial adhesions or labial coalescence, refers to adhesion of the small vaginal labia on the midline, often in upward direction. Physical examination often reveals a thin semitransparent pale membrane between the labia minora, sometimes obstructing the vaginal introitus (Figure 1). The condition has an incidence of 1.8–3.3% at two years of age and a peak between 13 and 23 months. However, several minor cases are likely to go unnoticed in regular observations, with some authors pointing real incidence rates as high as 40%. Tissue hypoestrogenism, more pronounced between the age of three months and six years, seems to be the most determining factor for development of this alteration, even though studies have not yet found a clear link between hypoestrogenism and incidence of this pathology.
Chronic vulvar inflammation, poor hygiene habits, infection, or genital trauma (including sexual abuse and female circumcision) may contribute to this alteration by acting on a hormonally propitious terrain.  

Diagnosis is clinical and usually asymptomatic. In some cases, the child may report local itching, pain, or genital discharge.  

Although rare, recurrent urinary and vulvovaginal infections are possible complications. Coalescence of labia minora may also interfere with genital hygiene.  

Urinary changes, as vaginal reflux, have been reported in most severe cases, although urinary retention is uncommon, since urine stream passage prevents labia adhesion in the urinary meatus area.  

An expectant attitude should be adopted in most cases, especially if asymptomatic and involving a small labia portion, thus not interfering with urine flux. High rate of spontaneous healing (about 80% in one year) is usually observed.  

In case of symptoms or complications, first-line treatment consists of application of topical estrogen 0.01% cream three times daily, applied in the fusion line with a small and downward traction massage, until adhesion resolution (usually two to four weeks). Efficacy of this treatment is however debatable and probably higher in relapse prevention. Treatment is generally well tolerated and with mild side effects, such as local hyperpigmentation, vaginal bleeding, and rarely breast augmentation, which resolve with treatment discontinuation.  

Topical betamethasone 0.05% applied in two to three cycles for four to six weeks is an effective and well tolerated treatment, with some studies reporting at least identical efficacy to local estrogen therapy. Manual lysis is commonly performed under sedation, to avoid pain and psychological trauma, although it can be done with topical anesthesia if the child accepts and cooperates. Vaseline, estrogen cream, or local emollient application is recommended after mechanical adhesion resolution to reduce recurrence, which occurs in around 14% of cases.  

Hypertrophy/asymmetry of vaginal labia  

Despite parents’ concern, in most cases this situation is a variant of normal.  

It is usually a transient finding in the newborn (edema of the labia majora), resulting from fluid accumulation in tissues.  

Hypertrophy of the labia minora can be associated with difficulties in genital hygiene, pain, or use of tight clothing. Reduction labiaplasty may be indicated in some cases, due to its important impact on quality of life, comfort, and self-image, but always after menarche.  

Clitoris hypertrophy  

Clitoral hypertrophy may be related to fetal exposure to androgens, usually resulting from congenital deficiency of cortisol synthesis enzymes in the adrenals, such as 21-alpha-hydroxylase deficiency (adrenal hyperplasia) or tumor testosterone producer. Suspected cases should first rule out sexual differentiation disturbances, which require referral to specialized consultation for hormonal study.  

Depending on hypertrophy degree, reduction clitoroplasty may be indicated.  

Congenital vaginal obstruction  

Congenital vaginal obstruction is often caused by imperforate hymen (0.5:1000) or more rarely by transverse vaginal septum (1:3000 to 1:80000) (Figure 2), in which case is frequently associated with Mullerian anomalies.  

Hemivagina obstruction by a longitudinal septum may also be present, a situation that may be associated with di-delphic uterus and unilateral renal agenesis (Herlyn-Werner-Wunderlich Syndrome).  

Diagnosis is difficult in the newborn, since an asymptomatic pattern due to mucus reabsorption is often the rule, and frequently goes unnoticed on physical examination of external genitalia.  

This condition may present as interlabial cysts, especially if the obstruction is caused by an imperforate hymen, causing lower abdominal swelling.  

![Figure 2 - Transverse vaginal septum in upper vagina (black arrow)](image-url)

Ultrasound is the exam of choice and diagnosis is often established at the time of menarche. By this time, blood accumulation is present in the vagina (hematocolpos) and/or uterus (hematometra), depending on the obstruction type and location. Primary amenorrhea occurs, as well as cyclic or continuous pelvic pain, and it is often possible to see an interlabial swelling or transverse septum on gynecological examination. CT or preferably MRI may be useful to characterize
the vaginal septum and associated structural abnormalities of the reproductive and urinary systems.\textsuperscript{18,19}
Excision or incision of the hymen or transverse septum is ideally performed prior to hematocolpos or hematometra development, but preferably after tissue estrogenization.\textsuperscript{20,21}

Genital polyps
Vaginal and hymenal polyps are rarely observed.
This condition is characterized by growth of "fingerlike" fleshy fibroepithelial tissue in the vagina or hymen, sometimes accompanied by genital discharge, being rare in newborns.\textsuperscript{22} Without immediate indication for surgical correction, lesion biopsy or excision should be considered to exclude malignancy, namely rhabdomyosarcoma.\textsuperscript{23}

Urethral eversion
Urethral eversion is a rare entity in girls and more frequently reported in the black race. It consists in eversion of a portion of the distal urethral mucosa through the external meatus, with a cleavage plane between the internal longitudinal and external circular-oblique smooth muscle layers of the urethra.\textsuperscript{24,25}
Urethral eversion can occur with perineal hemorrhage due to vascular congestion of the spongy body and dysuria, and with eversion of the urethral mucosa on physical examination.
Topical estrogen twice daily for three to four weeks and two-week sitz baths may be effective in mild cases.\textsuperscript{26,27}
Excision of prolapsed urethral mucosa and suturing of the remaining mucosa into vestibule is an option in more severe or nonresponsive cases.\textsuperscript{28}

Vulvar cysts
Vulvar cysts are rare in pre-pubertal children and often require pediatric gynecology evaluation.
Skene cysts (para-urethral cysts) are retention cysts secondary to inflammatory obstruction of the Skene ducts (usually asymptomatic and regressing between the 4th and 8th weeks).\textsuperscript{29,30}
Gartner cyst is a remnant of the Wolff duct, being most common in the lateral and posterior portion of the vagina.\textsuperscript{31}
Bartholin gland cyst occurs when drainage from this gland is blocked, with subsequent inflammation.
Cysts are usually identified in physical examination and present as inter-labial masses.
Treatment is conservative in asymptomatic cases, requiring antibiotics in case of infection. Drainage/marsupialization/surgical excision may be indicated.\textsuperscript{32}

Botryoid sarcoma
Botryoid sarcoma corresponds to an embryonal rhabdomyosarcoma subtype and is the most frequent neoplasia of the female genital tract in childhood, accounting for approximately 5% of all children malignancies.\textsuperscript{33}
It presents as polypoid and multilobular, smooth-surface tumors often resembling a bunch of grapes, which protrude through the vagina and lead to abnormal vaginal bleeding and leucorrhea.\textsuperscript{34}
The most common metastatic sites are the lungs, liver, and bone marrow.
Referral for biopsy and histological examination is paramount in this type of lesion, and treatment is individualized and consists of a combination of surgery, radiotherapy, and chemotherapy.\textsuperscript{35}

Prolapse of ectopic ureterocele
Ureterocele is a cystic dilation of the terminal ureter that can dictate varying degrees of ureteral obstruction, being more frequent in girls. It is termed ectopic ureterocele when prolapse extends from the bladder neck to the urethra.
Diagnosis is often established in prenatal ultrasound and can be associated with ureteral duplication, with frequent drainage of the superior renal pole.
Ectopic ureterocele may rarely cause bilateral urinary obstruction and may insinuate through the urethral meatus, thus becoming visible on physical examination of female pediatric patients.\textsuperscript{36,37}
Treatment is surgical, with presence of lower ureteral reflux representing an important factor determining the approach.\textsuperscript{38-40}

CONCLUSION
Anatomic genital pathology in prepubertal children is most often diagnosed by systematic and careful physical examination and in most cases has a very favorable outcome. Although these situations cause increased anxiety in parents due to their meaning, it is the physician’s role to reassure parents and clarify the condition’s meaning. When necessary, implementing simple and feasible therapeutic measures in primary health care is often enough to solve the problem, which in many cases is self-limited.
It is also the responsibility of the family physician to identify situations which, due to their less favorable evolution, complexity, or potential functional or emotional impairment, require timely referral for specific diagnostic study, implementation of therapeutic measures, or even specialized surveillance.
In most cases, with implementation of the correct measures, prognosis of genital pathologies in the pre-pubertal child is favorable.
